Abstract

We discuss numerical solution of Altarelli-Parisi equations in a Laguerre-polynomial method and in a brute-force method. In the Laguerre method, we get good accuracy by taking about twenty Laguerre polynomials in the flavor-nonsinglet case. Excellent evolution results are obtained in the singlet case by taking only ten Laguerre polynomials. The accuracy becomes slightly worse in the small and large x regions, especially in the nonsinglet case. These problems could be implemented by using the brute-force method; however, running CPU time could be significantly longer than the one in the Laguerre method.

1. Introduction

In order to investigate nucleon substructure, we scatter high-energy electrons or muons from the proton target. Its cross section is expressed in term of two unpolarized structure functions F_1 and F_2, which depend on two kinematical variable x and Q^2. If the nucleon consists of free partons, the structure functions are independent of the variable Q^2. This assumption is called Bjorken scaling hypothesis. However, it is well known that the structure functions do depend on Q^2 experimentally and theoretically. This fact is called "scaling violation", which is important in testing perturbative QCD. The scaling violation results from the fact that high-energy photons probe minute $q\bar{q}$ clouds around a quark.

An intuitive way to describe the phenomena is to use the Altarelli-Parisi equation. The flavor-nonsinglet Altarelli-Parisi equation is given by

$$\frac{d}{d\ln Q^2} \, q_{NS}(x, Q^2) = \frac{\alpha_s(Q^2)}{2\pi} \int_x^1 \frac{dy}{y} \, P_{NS}\left(\frac{x}{y}\right) \, q_{NS}(y, Q^2) \quad , \tag{1.1}$$

where $q_{NS}(x, Q^2)$ is a nonsinglet quark distribution, $\alpha_s(Q^2)$ is the running coupling constant, and $P_{NS}(x)$ is a nonsinglet splitting function. The above equation describes the process that a quark with the nucleon's momentum fraction y radiates a gluon and it becomes a quark with the momentum fraction x. The splitting function $P_{NS}(z)$ determines the probability for a quark radiating a gluon such that the quark momentum is reduced by the fraction z. Next-to-leading-order corrections to the Altarelli-Parisi

equation are included in the coupling constant α_s and in the splitting function P_{NS}. The leading order and the next-to-leading order are abbreviated to LO and NLO respectively throughout this paper.

The singlet Altarelli-Parisi equations are coupled integrodifferential equations:

$$\frac{d}{d\ln Q^2} q_S(x, Q^2) = \frac{\alpha_s}{2\pi} \int\limits_x^1 \frac{dy}{y} \left[P_{qq}\left(\frac{x}{y}\right) q_S(y, Q^2) + P_{qG}\left(\frac{x}{y}\right) G(y, Q^2) \right] \quad ,$$

$$\frac{d}{d\ln Q^2} G(x, Q^2) = \frac{\alpha_s}{2\pi} \int\limits_x^1 \frac{dy}{y} \left[P_{Gq}\left(\frac{x}{y}\right) q_S(y, Q^2) + P_{GG}\left(\frac{x}{y}\right) G(y, Q^2) \right] \quad , \quad (1.2)$$

where $q_S(x, Q^2)$ is the singlet quark distribution $q_S \equiv \sum\limits_{i=1}^{N_f}(q_i + \bar{q}_i)$ and $G(x, Q^2)$ is the gluon distribution. $P_{qq}(x)$, $P_{qG}(x)$, $P_{Gq}(x)$, and $P_{GG}(x)$ are splitting functions.

Because the Q^2 evolution equations are very important for testing perturbative QCD and are often used theoretically and experimentally, it is worth while having a computer program of solving it accurately without consuming much computing time. Our research purpose is to create a useful computer program for numerical solution of the Altarelli-Parisi equations. There are several methods in solving the equations; however, a Laguerre-polynomial method is considered to be very effective among them [1]. In Ref. [2], we provide the Laguerre method program LAG2NS, which deals with the Q^2 evolution of a nonsinglet distribution in the next-to-leading order. In this paper, we show Laguerre-method results in Ref. [2] and compare them with results in a brute-force method [3].

In section 2, we explain the Laguerre method for solving the evolution equations with NLO corrections. The brute-force method is discussed in section 3 and conclusions are given in section 4.

2. Laguerre-polynomial method

2.1 Nonsinglet distribution

The Laguerre-polynomial method is considered to be effective in convergence and in computing time. This is because the first several polynomials resemble parton distributions. Numerical solution for the evolution equation including the NLO corrections is discussed in the following. We refer the reader to the papers in Refs. [1, 2] for more complete account of the Laguerre method. The NLO running coupling constant is used in this paper unless we specify LO. The renormalization scheme is $\overline{MS}$.

We first define the variable t and the evolution operator $E(x, t)$ by $t = -\frac{2}{\beta_0} \ln\left[\frac{\alpha_s(Q^2)}{\alpha_s(Q_0^2)}\right]$ and

$$\tilde{q}_{NS}(x, t) = \int_x^1 \frac{dy}{y} E(\frac{x}{y}, t) \tilde{q}_{NS}(y, t = 0) \quad , \quad (2.1)$$

where $\widetilde{q}$ is given by $\widetilde{q}(x) = xq(x)$. The function $E(x,t)$ describes the Q^2 evolution from the initial distribution at Q_0^2 ($t = 0$) to the one at Q^2. Substituting Eq. (2.1) into the Altarelli-Parisi equation in Eq. (1.1), we find that the evolution operator satisfies

$$\frac{d}{dt} E(x,t) = \int_x^1 \frac{dy}{y} \left[\widetilde{P}_{NS}^{(0)}(\frac{x}{y}) + \frac{\alpha_s(t)}{2\pi} R(\frac{x}{y}) \right] E(y,t) \quad , \tag{2.2}$$

where $\widetilde{P}(x) = xP(x)$ and $R(x)$ are given by $R(x) = \widetilde{P}_{NS}^{(1)}(x) - \frac{\beta_1}{2\beta_0} \widetilde{P}_{NS}^{(0)}(x)$. $P_{NS}^{(0)}(x)$ and $P_{NS}^{(1)}(x)$ are LO and NLO splitting functions. The function $E(x,t)$ is split into LO and NLO contributions by $E(x,t) = E^{(0)}(x,t) + \frac{\alpha_s(0)}{2\pi} E^{(1)}(x,t)$. Substituting this into Eq. (2.2) and considering that the LO evolution operator $E^{(0)}(x,t)$ satisfies the LO Altarelli-Parisi equation, we find that the LO and NLO evolution operators are not independent and they are related by

$$E^{(1)}(x,t) = \frac{2}{\beta_0} \left[1 - \frac{\alpha_s(t)}{\alpha_s(0)} \right] \int_x^1 \frac{dy}{y} R\left(\frac{x}{y}\right) E^{(0)}(y,t) \quad . \tag{2.3}$$

The variable x' is introduced by $x' = -\ln x$ ($0 \leq x \leq 1$) in order to use the Laguerre polynomials, which are defined in the region $0 \leq x' < \infty$. Using the variable x', we expand the functions in terms of the Laguerre polynomials: $f(x = e^{-x'}) = \sum_n f_n L_n(x')$. Then, the problem is to obtain the expansion coefficients E_n in terms of the coefficients P_n of the splitting function. The LO evolution operator is given in Ref. [1] by $E_n^{(0)}(t) = e^{P_0 t} \sum_{k=0}^{N_{max}} \frac{t^k}{k!} B_n^k$, where B_n^k is calculated by the recurrence relation $B_n^{k+1} = \sum_{i=k}^{n-1}(P_{n-i} - P_{n-i-1})B_i^k$ with $B_i^0 = 1$, $B_i^1 = \sum_{j=1}^{i}(P_j - P_{j-1})$, $B_0^k = B_1^k = \cdots = B_{k-1}^k = 0$.
The NLO evolution operator is given by using the calculated $E_n^{(0)}(t)$ and Eq. (2.3):

$$E_n^{(1)} = \frac{2}{\beta_0} \left[1 - \frac{\alpha_s(t)}{\alpha_s(0)} \right] \sum_{i=0}^{n} (R_{n-i} - R_{n-i-1}) E_i^{(0)}(t) \quad , \tag{2.4}$$

where R_i are the Laguerre coefficients of $R(x)$, and R_{-1} is defined as $R_{-1} = 0$. Using these results, we finally obtain

$$\widetilde{q}_{NS}(x,t) = \sum_{n=0}^{N_{max}} \sum_{m=0}^{n} \left[E_{n-m}(t) - E_{n-m-1}(t) \right] L_n(-\ln x) \widetilde{q}_{NS,m}(t=0) \quad , \tag{2.5}$$

with $E_n(t) = E_n^{(0)}(t) + \frac{\alpha_s(0)}{2\pi} E_n^{(1)}(t)$. In this way, the original integrodifferential equation is reduced to a sum of finite number of Laguerre expansion coefficients and the Laguerre polynomials.

We have discussed the Q^2 evolution of a nonsinglet quark distribution. Q^2 evolution of a nonsinglet structure function is calculated in a similar way. The only modification is to take into account NLO corrections from the coefficient function. A nonsinglet structure function $F_{NS}(x, Q^2)$ is expressed as a convolution of the corresponding nonsinglet quark distribution $q_{NS}(x, Q^2)$ and the coefficient function $C_{NS}(x, \alpha_s)$ as [4]

$$F_{NS}(x, Q^2) = \int_x^1 \frac{dy}{y} \, C_{NS}(\frac{x}{y}, \alpha_s) \, q_{NS}(y, Q^2) \quad . \tag{2.6}$$

C_{NS} is given by $C_{NS}(x, \alpha_s) = \delta(1-x) + \frac{\alpha_s}{4\pi} B^{NS}(x)$, where $B^{NS}(x)$ is the NLO correction. We show examples of our evolution results [2] in the following.

The initial distribution is given by the HMRS-B valence-quark distribution at Q^2=4 GeV^2 [5]. This distribution is evolved to the one at Q^2=200 GeV^2. Evolved distributions are shown in Fig. 1. We find that accurate results are obtained by taking about twenty Laguerre polynomials; however, the accuracy becomes slightly worse in the very small x region ($x < 0.001$) and in the very large x region ($x > 0.9$).

Our evolution results are compared with the CDHSW neutrino data [6] in Fig. 2. The CCFR $F_3(x)$ distribution at Q^2=3 GeV^2 [7] is chosen as the initial distribution in both LO and NLO cases. We employ Λ=0.21 GeV and four flavors for calculating the evolution. The NLO contributions are important at small Q^2 (≈ 1 GeV^2) and at small x as shown in Fig. 2. Furthermore, the figure indicates that our Q^2 variations are consistent with the CDHSW experimental data.

Fig. 2 Q^2 evolution of F_3.

2.2 Singlet distribution

The nonsinglet evolution is rather simple because gluons do not participate in the evolution process. However, the singlet part is more complicated because the Altarelli-Parisi equations are coupled integrodifferential equations in Eq. (1.2). We do not discuss formalism of singlet solution, so interested reader may read the papers in Ref. [1]. Even though the analysis is slightly complicated, the essential procedure is the same as the one in the previous subsection. Our investigation for the singlet part is still in progress [2], so the results in this subsection should be considered as preliminary ones. Calculating Laguerre-expansion coefficients for the splitting functions in Eq. (1.2) and for initial distributions, we obtain a solution similar to Eq. (2.5).

The initial singlet distribution $q_s(x)$ and gluon distribution $G(x)$ are chosen as the HMRS-B distributions at $Q^2=4$ GeV^2. They are evolved to the ones at $Q^2=200$ GeV^2. Three evolution results are shown by taking five, ten, and twenty Laguerre polynomials in Figs. 3 and 4. It is rather surprising to find excellent accuracy even at very small x as small as 10^{-4}. The accuracy is much better than the nonsinglet one by taking only ten Laguerre polynomials.

Typical running time is a few seconds on SUN-IPX or on VAX-4000/500 in obtaining a x-distribution curve in Fig. 1, 3, or 4. Considering the excellent accuracy and the short running time, we conclude that the Laguerre method is very effective for numerical solution of the Altarelli-Parisi equations.

3. Brute-force method

The Laguerre method is practically useful; however, it does not produce excellent results at small x and at large x in the nonsinglet case. With development of high-energy accelerators, the small x region becomes more and more interesting. For those who are serious about the small x and large x regions, we discuss an alternative method, the brute-force method in Ref. [3], for obtaining accurate numerical solution.

The brute-force method is perhaps the simplest one in solving the integrodifferential equation. We divide the variables t and x into small steps, then the derivative by t is defined as

$$\frac{d}{dt} q(x,t) \;\Rightarrow\; \frac{q(x_i, t_{j+1}) - q(x_i, t_j)}{\Delta t} \quad , \tag{3.1}$$

and the integral over y is by

$$\int_x^1 \frac{dy}{y} \; P(\frac{x}{y}) \; q(y,t) \;\Rightarrow\; \sum_{k(=i)}^{N_x} \frac{\Delta x}{x_k} \; P(\frac{x_i}{x_k}) \; q(x_k, t_j) \quad . \tag{3.2}$$

If the number N_x is increased, we expect to obtain accurate numerical results. However, numerical convergence is not good in the small x region even if we take large N_x. So we decide to divide x into equal steps in the logarithmic scale. Then, our evolution results converge by taking large $N_x \approx 200$. Evolution results of the HMRS-B valence-quark distribution are shown in Fig. 5 by taking N_x=50, 200, 500 with fixed number of points N_t=100 for the variable t. The accuracy is excellent in the nonsinglet distribution, so the brute-force method could be used in the small x region instead of the Laguerre method. However, it takes significant amount of running CPU time as shown in Fig. 6.

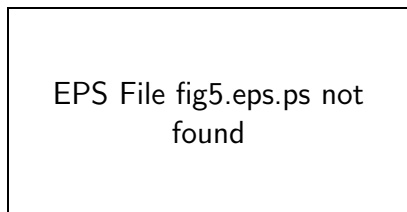

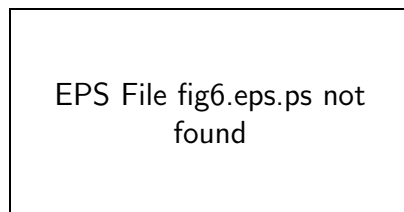

Fig. 5 Q^2 evolution of $x(u_v + d_v)$.

Fig. 6 Computing time.

4. Conclusions

We investigated numerical solution of the Altarelli-Parisi equations with next-to-leading-order corrections in the Laguerre-polynomial and the brute-force methods. Excellent convergence is obtained in the singlet case by using the Laguerre method with merely ten Laguerre polynomials. The accuracy is slightly worse in the nonsinglet case especially at small and large x. However, accurate results are obtained in these regions by using the brute-force method.
